### ABSTRACT

When coupled to acoustics, unsteady heat release oscillations may cause recurrent problems in many combustion chambers, potentially leading to dramatic damages to the structure. Accumulation of acoustic energy around the eigenmodes of the combustor results from the resonant coupling between pressure disturbances in the flame region with synchronized heat release rate perturbations. Predicting these frequencies and the corresponding sound pressure field is a key issue to design passive or active control systems to prevent the growth of these instabilities. In this study, an acoustically controlled combustion test bench CESAM is used to stabilize a partially premixed swirling propane–air flame. In the premixing tube, reactants are injected tangentially to generate the swirling flow, the flame being stabilized in the combustion chamber by a sudden expansion of the cross section. The premixer backplane is equipped with an Impedance Control System (ICS) allowing to adjust the acoustic reflection coefficient at this location. Acoustics of the coupled-cavity system formed by the premixer and the combustion chamber is investigated analytically by taking into account the measured acoustic impedances at the premixer backplane and in the feeding lines. The chamber length is also modified to examine the effects of the geometry on these predictions. It is shown that the premixer and combustion chamber can be considered as acoustically decoupled for small values of the acoustic coupling index, defined in the article. This offers flexible solutions to control the pressure distribution within the combustor, except when these frequencies match. When the frequencies are close to each other, only the analysis of the damping of the different cavities enables to indicate whether the system is coupled or not. Modifying either the acoustic coupling index or the damping values featuring the same frequency appears then as alternative solutions to decouple cavities.

### R É S U M É

Les instabilités de combustion posent des problèmes récurrents dans les foyers de combustion et peuvent causer des dommages importants et irréversibles aux structures. L'accumulation d'énergie acoustique au voisinage des modes propres du système résulte d'un couplage résonant entre les perturbations de pression et du taux de dégagement de chaleur dans la zone de réaction. La prévision de ces fréquences et du champ acoustique associé est importante pour optimiser la conception des systèmes de contrôle actif ou passif empêchant l'amplification de ces instabilités. Dans cette étude, le banc de combustion CESAM est utilisé pour stabiliser des flammes propane–air swirlées partiellement prémélangées. Dans le tube de prémélange, les gaz frais sont injectés tangentiellement pour mettre en rotation l'écoulement, la flamme étant stabilisée dans

la chambre de combustion par un changement brusque de section. Le fond du tube de mélange est équipé d'un système de contrôle d'impédance (ICS) permettant d'ajuster le coefficient de réflexion acoustique. L'acoustique de ce système de cavités couplées est étudiée analytiquement en prenant en compte l'impédance acoustique mesurée au fond du tube de prémélange et dans les lignes d'alimentation. La longueur de la chambre est aussi modifiée pour examiner les effets de la géométrie sur ces prévisions. On montre que le tube de prémélange et la chambre peuvent être considérés comme acoustiquement découplés pour des valeurs faibles de l'indice de couplage défini ici. Ceci n'est cependant pas valable dans la région où les fréquences sont voisines. Dans ce cas, seule l'analyse de l'amortissement de chacun des modes permet de déterminer si les deux cavités sont couplées ou non. Il est par conséquent possible de découpler acoustiquement deux cavités en jouant sur l'indice de couplage ou bien en modifiant l'amortissement de l'une des cavités lorsque leurs fréquences propres sont proches.

## 1. Introduction

Analysis of the acoustic modes of a combustor is often a preliminary and necessary step before envisaging the prediction of acoustically coupled combustion instabilities and resulting combustion noise production [1,2]. It is well known that the frequencies of unstable combustion oscillation modes lie close to the acoustic modes of the combustion system [3–6]. The determination of the acoustic modes and the corresponding sound pressure distributions are also important issues to identify the possible locations of passive and active control devices to hinder these self-sustained oscillations [7,8].

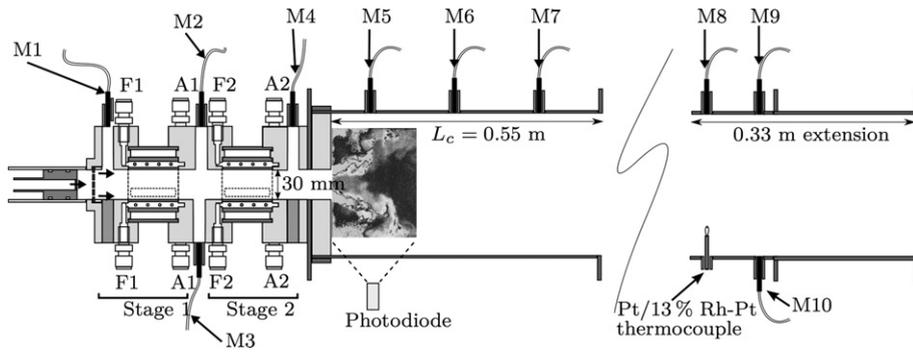

This problem does not require to solve the full compressible unsteady Navier–Stokes equations, and simpler alternatives have been developed. A current approach adapted to complex geometries is to solve the Helmholtz equation [9,10] or the linearized Euler equations [11,12] when mean flow effects cannot be neglected. This type of simulations now include local modifications of the mean sound celerity due to changes in the gases composition and temperature throughout the combustor [13,14] and complex impedances at the boundaries [15]. It is also possible to account for acoustic dissipation [16] or effects of dampers [17,18].

At low frequencies, only longitudinal waves propagate and geometrical details do not need to be considered in the models. Networks of compact acoustic elements constitute then an interesting low order solution to model the combustor acoustics [19,20]. In this case, it is also useful to develop an analytical representation of the system studied to gain insight on the physics and easily determine the main governing parameters controlling the acoustics of these coupled cavities. This problem has for example been envisaged by Tran [21] and later by Lamraoui [22] to model the acoustic response of a swirled injector in a premixing tube connected to a combustion chamber. The originality of this setup is that it is equipped with a perforated plate and a back cavity at the premixer inlet location that are used to control its impedance. It was found by Tran et al. [23,24] that this constitutes an efficient way to damp low-frequency unstable modes reaching a sound pressure level up to 140 dB in a gas turbine model combustor operated at thermal powers ranging from 30 to 65 kW. By modifying the premixer inlet impedance, it was possible to reduce the sound level by about one order of magnitude in all cases explored for the same flow operating conditions. This is also demonstrated numerically by Gullaoud and Nicoud [25]. In the present study, a theoretical analysis is conducted to model the acoustic response of this test rig and examine effects of changes of the premixer inlet impedance and modifications of the chamber length on the sound pressure distribution in the combustor. Predictions are then compared to measurements obtained under reactive conditions for two chamber lengths and different inlet reflection coefficients. On a control point of view, the objective is to show that it is possible to damp unstable modes coupled to the premixer or combustion chamber cavities by only modifying the premixed inlet boundary condition.

In Section 2, the experimental setup and diagnostics are presented. Two operating points are chosen for the present study with two different chamber lengths but with similar thermal power outputs. Acoustic measurements are presented in details in Section 3. In particular, Power Spectral Densities (PSD) and pressure distributions within the combustor are presented to highlight the effect of the chamber length on the acoustics. In Section 4, a two-cavity model is used to estimate the acoustic response of the combustor. In this description, each cavity represents one element of the combustor, the premixer and chamber, which are interconnected. The eigenmodes of this coupled system are compared to the modes of each cavity calculated separately. This analysis highlights the evolution of pressure distribution for the different geometries and operating conditions investigated. An improved version featuring five cavities taking into account effects of the feeding lines is proposed in the final section to account for acoustic dissipation.

## 2. Experimental setup

The experimental facility sketched in Fig. 1 is composed of a partially premixing cylindrical tube connected to a rectangular combustion chamber with a square  $10 \times 10 \text{ cm}^2$  cross section. The premixer is composed of two identical stages in which tangential injections of air and propane put the flow in rotation with a theoretical swirl number of 0.7 in the

**Fig. 1.** CESAM test bench fed with propane and air through two identical stages: each stage is fed with two inlets for propane (F1 for stage 1 and F2 for stage 2) and two inlets for air (A1 for stage 1 and A2 for stage 2). The locations of microphones M1 to M10, the photodiode and the thermocouple are also indicated.

**Table 1**

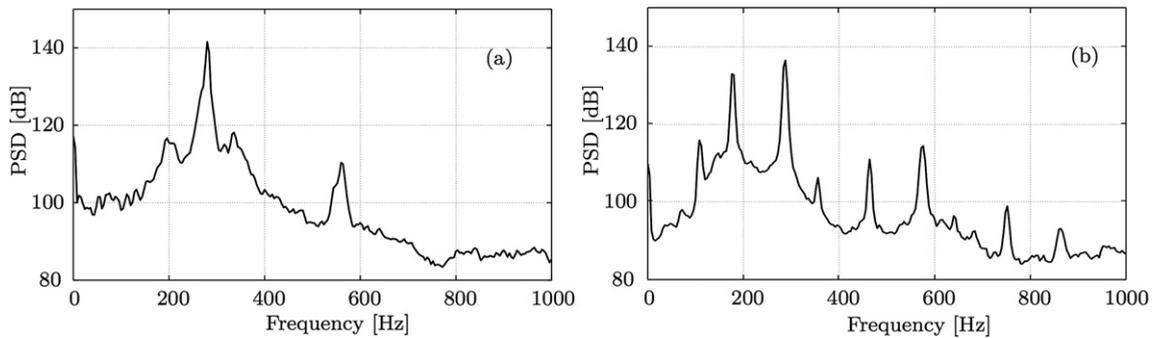

Operating points used in the present investigation. The equivalence and staging ratio were slightly modified for the two chamber lengths, the global thermal power being roughly kept constant.

	Chamber length [cm]	Equivalence ratio $\phi$	Staging ratio $\alpha$ [%]	Thermal power [kW]
Point 1	55	0.75	15	33
Point 2	88	0.80	50	35

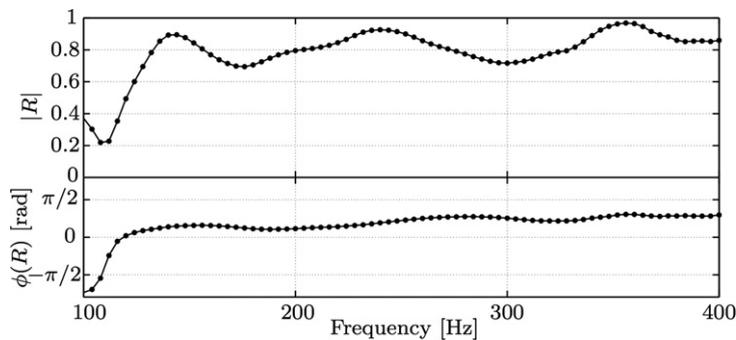

30-mm-diameter premixer. Each stage is fed with two air (A1–A2) and two fuel (F1–F2) supplying pipes that are connected to mass flow controllers through a pipe network. This burner operates in lean conditions for equivalence ratios  $\phi$  ranging between 0.7 and 0.95. It is connected to the combustion chamber through a ceramic junction. The chamber is composed of two quartz windows on each lateral side and refractory concrete walls on top and bottom. The premixing tube manifold has a length  $L_p = 23.5$  cm. It is equipped with acoustic waveguides connected to microphones M1, M2, M3 and M4 to characterize the pressure distribution in this element and the premixer inlet reflection coefficient. The top of the combustion chamber is also equipped with three regularly spaced waveguides connected to microphones M5, M6 and M7 to characterize the pressure distribution in this region. An additional element with the same type of arrangement connected to microphones M8, M9 and M10 can be used to analyze the sound pressure distribution with a longer chamber. For the same total mass flow injected  $\dot{m} = 14.75$   $\text{g s}^{-1}$ , this configuration features self-sustained combustion oscillations depending on the equivalence ratio  $\phi$  and the fuel staging ratio  $\alpha$ , defined as the ratio of the fuel mass flow in the stage furthest from the chamber (stage 1) to the total fuel mass flow injected. This staging parameter can be varied between 10 and 55%, beyond this latter value the swirling flame penetrates the premixing tube and heats dangerously the premixer (flashback risks). To prevent this risk inside the premixer, air is injected axially from the rear side of the burner with a reduced mass flow corresponding to a small fraction of the total tangential mass flow injected in the system ( $\approx 2.5\%$ ). This air flow is also used as the bias flow in the Impedance Control System defined below. The flame takes an inverted conical shape with a strong internal recirculation zone, typical of swirl-stabilized configurations. The flame is compact, about 15 cm long, and is shown at scale with the burner geometry in Fig. 1.

One specificity of this gas turbine model combustor is that the burner inlet is equipped with an Impedance Control System (ICS) composed of a perforated plate backed by an adjustable length cavity with a mean bias flow. This system can be used to easily tune the modulus of the reflection coefficient at the premixer inlet to the desired value even for high amplitude pressure fluctuations. This control system was adapted to the combustion facility and efficient damping of combustion instabilities was proved [23]. A more detailed analysis is now presented in the following section. At the outlet boundary, the chamber exhaust is a square end open to atmospheric conditions. The chamber length was modified in these experiments with an additional element featuring the same cross section. Two different chamber lengths are tested,  $L_c = 0.55$  m and  $L_c = 0.88$  m. When the chamber length is changed, the system features a different behavior both in terms of acoustics and aerodynamics for the same flow operating conditions. To obtain two identical flame positions in the chamber, the operating conditions were adjusted to yield the same flame length. They are listed in Table 1. In the two cases, the burner operates in lean unstable conditions with about the same thermal power.

This gas turbine model combustor was primarily designed to easily characterize the acoustic pressure distribution in the premixer, chamber and feeding lines during self-sustained combustion instabilities. Microphones M1, M2 and M3 are used to determine the premixer acoustic reflection coefficient  $R(0)$  at the burner inlet. Reconstruction of the impedance at this location requires a careful calibration in gain and phase of the microphones (B&K type 4938 1/4 inch) and the use of a switching technique [26]. The sampling duration was set in all experiments equal to  $T = 8$  s with a sampling rate of  $f_s = 16384$  Hz allowing enough data collection for spectral analysis in noisy environments. Additional Impedance Measurement Devices (IMD) can be included at different locations on the fuel and air feeding lines to measure their acoustic response [27]. These devices are rectangular and comprise an inner cylinder of the same diameter as the air or fuel supplying pipe in which

**Fig. 2.** Power spectral density of the sound pressure recorded by microphone M1 in the premixing tube. Left: operating point 1 ( $L_c = 0.55$  m). Right: operating point 2 ( $L_c = 0.88$  m).

**Fig. 3.** Evolution of the acoustic reflection coefficient  $R$  at the premixing tube backplane ( $x=0$ ) for frequencies from 100 to 400 Hz. The ICS is disabled: the cavity length behind the perforated plate is reduced to zero.

they are inserted. Three 1/4-inch microphones are flush mounted to get the reflection coefficient at the IMD outlet. These devices were all tested in the impedance tube ITHACA [24] with known termination impedances and the results obtained were in excellent agreement with expected theoretical predictions [22].

### 3. Acoustic measurements

The Power Spectral Density (PSD) of the acoustic pressure recorded by M1 is plotted in Fig. 2 for the two unstable operating points investigated corresponding to different chamber lengths. The spectrum on the left obtained for the short chamber features one dominant frequency peak at 280 Hz with a sound level higher than 140 dB. The secondary peaks reach lower levels around 120 dB (one order of magnitude below the main peak) with frequencies at 196 and 336 Hz. Only the main peak frequency 280 Hz will be considered in the following. On the right side of Fig. 2, the power spectral density in the premixer now features two main peaks at 180 and 280 Hz above 130 dB for the longer chamber. The secondary peaks lie in this case well below 120 dB and are not considered. This first observation indicates that the flame seems to amplify different incommensurate frequencies when the geometry of the chamber is changed. More details about the instability mechanisms leading to the two simultaneous unstable frequencies appearing in the long chamber configuration are given in Ref. [28]. In particular, it is shown in this reference that the two frequencies do not appear alternatively but co-exist over the total duration of the experiment.

Microphones located in the premixing tube allow one to reconstruct the acoustic reflection coefficient at the rear back plane of the premixer using a three-microphone method [26]. As described in the previous section, the rear backplane of the premixing tube is a perforated plate traversed by a low speed bias flow. The length of the cavity behind this plate can be adjusted to vary the reflection coefficient. When the ICS is disabled, the cavity length is set to zero but the bias flow is conserved through the perforations. Thus the reflection coefficient does not exactly match a perfectly reflecting wall. Black circles in Fig. 3 show the reflection coefficient deduced from the acoustic pressure measurements in the premixing tube when the ICS is disabled as a function of frequency. The phase first increases rapidly at low frequencies ( $f > 100$  Hz) and then features a regular increase up to 1 rad, reached at  $f = 120$  Hz. The modulus of the reflection coefficient increases rapidly from 0.2 to 0.9 for low frequencies and then oscillates between 0.7 and 0.9. At the resonant frequencies observed in the experiment (around 280 Hz for the short chamber, 180 and 280 Hz for the long chamber), the modulus is close to 0.8 and the phase is 0.75 rad.

The same types of impedance measurements were carried out in the fuel and air feeding lines with IMD as described in [27]. It is found that the pressure oscillations are still present in the feeding lines up to several meters upstream the

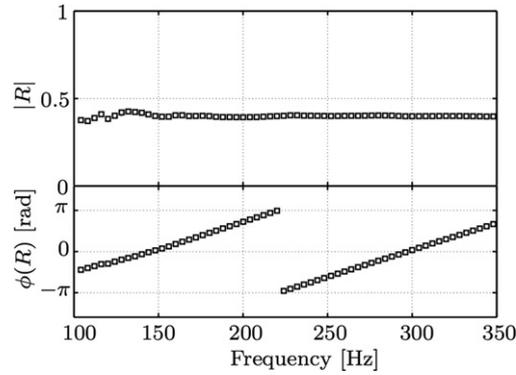

Fig. 4. Measurement of the acoustic reflection coefficient in the air feeding lines at 30 cm from the junction point between the lines and the premixing tube.

premixer. It is only at the flow controller boundaries that these waves are filtered and that the corresponding oscillations disappear in the pressure spectrum. Thus the acoustic reflection coefficient at the exit of the flow controller has an influence on the acoustics of the feeding lines. An IMD allows to determine the reflection coefficient in the feeding lines 30 cm away from the connection point between the supplying pipes and the premixer. Fig. 4 presents the evolution of the modulus and phase of this reflection coefficient with respect to frequency. The modulus remains here essentially constant over the frequency range investigated ( $|R| \simeq 0.4$ ), while the phase features a regular increase with frequency. These measurements were obtained *in situ*, meaning that there is no external acoustic forcing. The only acoustic source is due to the flame. In this situation, the acoustic modulation is not constant in amplitude with the frequency so that non-linear effects may slightly interfere and modify these results. Additional measurements of the flow controllers impedance were thus carried out on an acoustically controlled test bench to crosscheck the results [27]. Finally, the impedance at the outlet of the combustion chamber was also measured and does not differ from theoretical predictions if a correction length  $\delta = 0.85r_h$  is added to the chamber length, where  $r_h = 2.12$  cm indicates the hydraulic radius of the square combustion chamber cross section.

This set of measurements enable to analyze the acoustics of the combustor using a multi-cavity model that takes into account the measured acoustic impedances at the different boundaries. This model and the corresponding predictions are presented in the next section.

#### 4. Influence of the premixer inlet reflection coefficient

The combustor is modeled by a five-cavity model representing the premixing tube, the feeding lines and the combustion chamber as shown in Fig. 5. All variables are decomposed in mean and harmonic fluctuating components,  $a = \bar{a} + a'$  with  $a' = \hat{a} e^{-i\omega t}$ , where  $\omega = 2\pi f + i\omega_i$  denotes the complex angular frequency. The model takes into account neither the mean flow nor the flame transfer function, thus the growing factor given by the imaginary part of the angular frequency can only take negative or null values in this description. The mean flow in the premixing tube never exceeds  $30 \text{ m s}^{-1}$  meaning that the Mach number remains below 0.085. The premixing tube and the feeding pipes are kept at a constant temperature  $T_p = 300$  K while the mean temperature in the combustion chamber is taken equal to  $T_c = 1200$  K in this model. This value corresponds to a mean temperature taking into account various measurements carried out at different locations in the combustion chamber. Acoustic pressures are written as:

$$\hat{p}_i = p_i^+ e^{ik_i x} + p_i^- e^{-ik_i x} \quad \text{and} \quad \hat{p}_j = p_j^+ e^{ik_j y} + p_j^- e^{-ik_j y}$$

where  $i$  equals 1, 2 and 3 in the premixing tube before the injection lines ( $x < L_1$ ), in the premixing tube after the injection lines ( $L_1 < x < L_p$ ) and in the combustion chamber ( $x > L_p$ ) respectively. Subscript  $j$  becomes  $t$  in the top feeding line and  $b$  in the bottom line. The model features ten unknowns which are linked by equations standing for boundary conditions and acoustic conservation laws at the different interfaces. Four equations are obtained by using the reflection coefficient measured at the premixer inlet, combustor outlet, top and bottom air feeding lines. Six equations are obtained by continuity of the acoustic volume flowrate and pressure at the feeding line junctions ( $x = L_1$ ) and at the end of the premixing tube ( $x = L_p$ ). Non-trivial solutions of the system are obtained when its determinant is zero which allows to determine the eigenfrequencies of the combustor.

The ICS is a key element to control the stability of the combustor. The influence of its acoustic properties is first investigated analytically. In this analysis, the influence of the feeding pipes is not taken into account. The model then degenerates to a system of two coupled cavities representing the premixing tube and the chamber. Acoustic interaction between these two cavities is then controlled by the acoustic coupling index [21]:

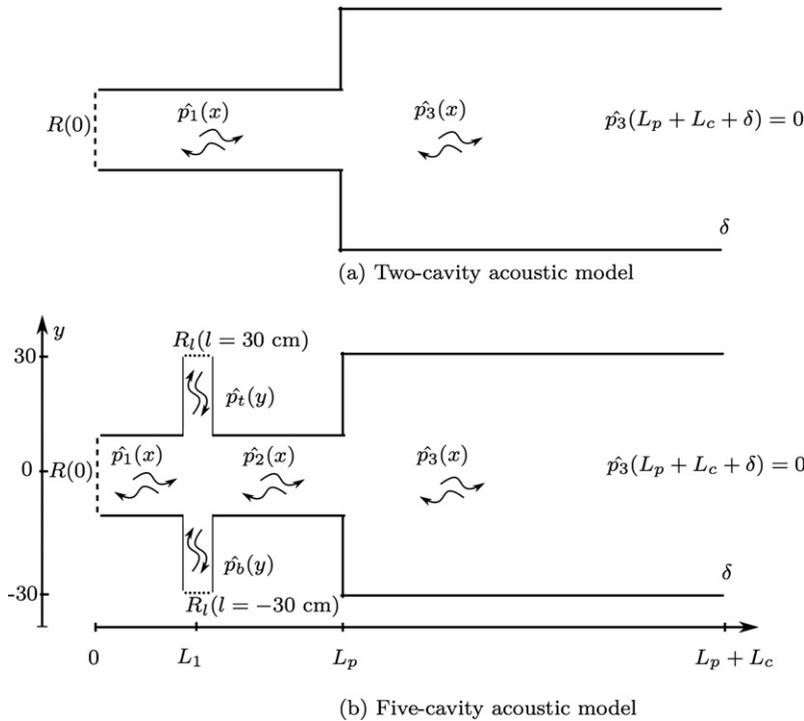

Fig. 5. The two acoustic models of the CESAM bench. Inlets are characterized by their acoustic reflection coefficient, the exhaust is open to ambient with the length correction  $\delta$ .

$$\mathcal{E} = \frac{S_p \rho_c c_c}{S_c \rho_p c_p} \simeq \frac{S_p}{S_c} \sqrt{\frac{T_p}{T_c}}$$

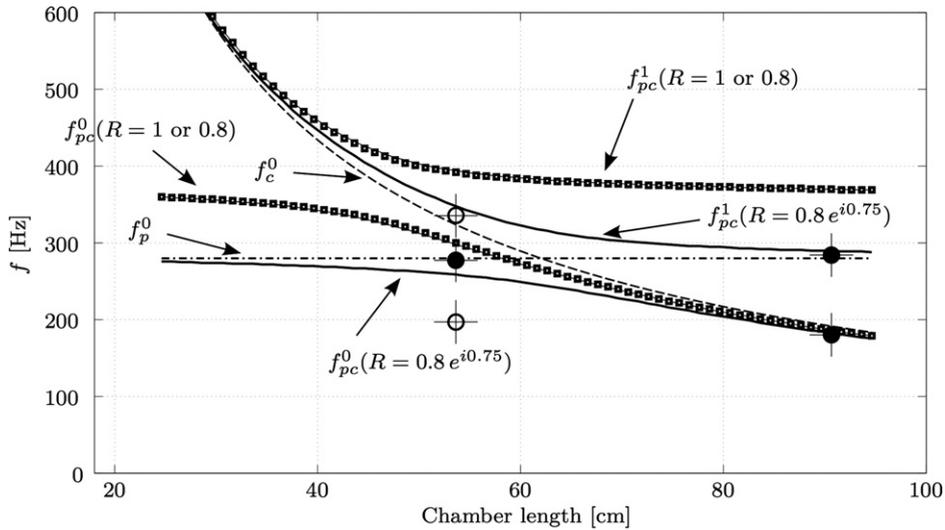

In the present experimental conditions,  $\mathcal{E} = 0.04$  takes a small value, indicating that acoustic coupling between the two cavities is weak. The combustor eigenmodes can then be linked to the pre-mixer and chamber modes calculated separately, corresponding to the solutions of the two coupled systems when  $\mathcal{E}$  is set to zero. The first eigenfrequency of the chamber  $f_c^0$  corresponds to a quarter-wave resonator, the first eigenfrequency of the pre-mixer is a quarter-wave resonator with a reflection coefficient  $R = |R| e^{i\varphi}$  at the backplane thus:

$$f_p^0 = \frac{c_p}{4L_p} \left( 1 - \frac{\varphi}{\pi} \right) \quad \text{and} \quad f_c^0 = \frac{c_c}{4L_c}$$

$c_p$  and  $c_c$  indicating the speed of sound in the pre-mixer (length  $L_p$ ) and the chamber (length  $L_c$ ) respectively. These frequencies  $f_p^0$  and  $f_c^0$  are plotted in Fig. 6 (dashed lines) as a function of the chamber length varying from  $L_c = 25$  to 90 cm. The first frequency  $f_p^0$  is independent on the chamber length and is equal to 281 Hz. The eigenfrequency of the chamber cavity  $f_c^0$  naturally decreases with the chamber length. The two curves cross each other when the chamber length is equal to  $L_c = 62$  cm, a value which is close to the short chamber length  $L_p = 55$  cm tested here.

The two-cavity model can also be used to compute the first two eigenfrequencies  $f_{pc}^0$  and  $f_{pc}^1$  of the system by taking into account the finite value of the coupling index  $\mathcal{E} = 0.04$  for different chamber lengths and reflection coefficients at the pre-mixer backplane. This backplane is first considered as a wall when  $R = 1$ ; calculations are then reconducted with the values measured for the modulus and phase of the pre-mixer reflection coefficient  $R = 0.8 e^{i0.75}$  taken near the pre-mixer eigenfrequency  $f_p^0 = 280$  Hz. The evolution of the two frequencies  $f_{pc}^0$  and  $f_{pc}^1$  is plotted in Fig. 6 as a function of the combustion chamber length for different estimates of the pre-mixer inlet reflection coefficient. These analytical predictions are also compared to the frequency peaks measured in the sound pressure spectra for the two chamber lengths  $L_c = 55$  cm and  $L_c = 88$  cm. Values for the different eigenfrequencies obtained for these two geometrical configurations are listed in Table 2.

The eigenfrequencies computed for  $R = 1$  or  $R = 0.8$  show a similar evolution in Fig. 6. Modifying the value of the modulus of the pre-mixer inlet reflection coefficient has no effect on the evolution of these frequencies when the chamber length is modified. The first frequency  $f_{pc}^0$  lies relatively close to one of the measured peak frequencies for the two combustor lengths explored. In this situation, the second eigenfrequency  $f_{pc}^1$  lies however always far away from any measured peak frequency and is overestimated for the two chamber lengths. The difference reaches about 100 Hz for the long chamber.

**Fig. 6.** Eigenfrequencies of the combustor obtained with the two-cavity model as a function of the chamber length  $L_c$  for different acoustic reflection coefficients at the premer inlet:  $R = 1$ ,  $R = 0.8$  and  $R = 0.8 e^{i0.75}$ . The first eigenfrequencies of the premer  $f_p^0$  and chamber  $f_c^0$  calculated separately are also plotted (dashed lines). Experimental data gathered for  $L_c = 55$  and  $88$  cm are indicated with crossed circles: filled circles feature the loudest peak frequency in the spectrum while the empty circles stand for secondary peaks.

**Table 2**

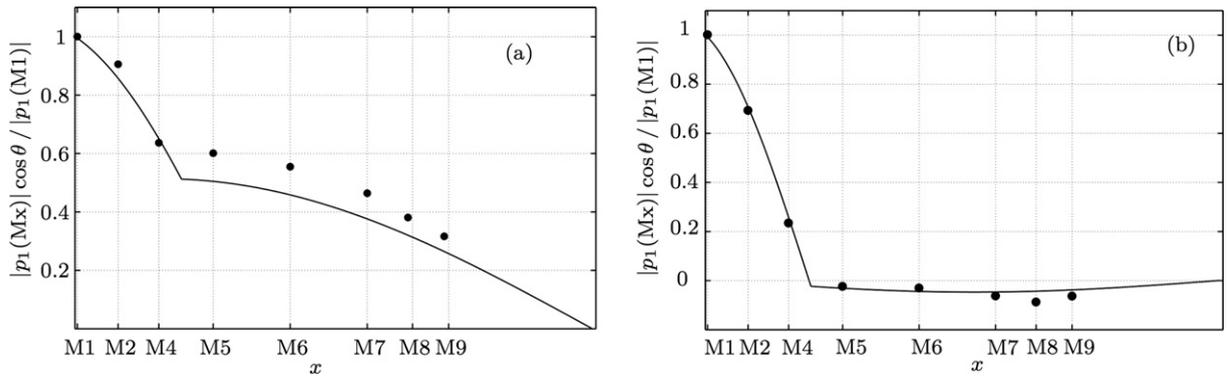

Evolution of the first eigenfrequencies  $f_{pc}^0$  and  $f_{pc}^1$  (in Hz) of the combustor for different premer inlet reflection coefficients  $R(0)$  and chamber length  $L_c$  obtained with the two-cavity model and compared with experimental results. The evolution of the first eigenfrequencies of the premer ( $f_p^0$ ) and chamber ( $f_c^0$ ) cavities calculated separately is also indicated.

	$L_c$	$f_c^0$	$f_p^0$	$f_{pc}^0$	$f_{pc}^1$
$R(0) = 1$	0.55	322	369	300	395
$R(0) = 0.8$	0.55	322	369	300	395
$R(0) = 0.8 e^{i0.75}$	0.55	322	281	<b>258</b>	349
Experiment	0.55	×	×	280	×
$R(0) = 1$	0.88	191	369	186	370
$R(0) = 0.8$	0.88	191	369	186	370
$R(0) = 0.8 e^{i0.75}$	0.88	191	281	<b>183</b>	<b>290</b>
Experiment	0.88	×	×	180	284

By taking into account the measured phase of the premer inlet reflection coefficient  $R = 0.8 e^{i0.75}$  in the two-cavity model, the eigenfrequencies  $f_{pc}^0$  and  $f_{pc}^1$  are displaced. As shown by the continuous lines in Fig. 6, the phase of the reflection coefficient has a strong effect on the eigenfrequencies evolution. The first mode  $f_{pc}^0$  tends towards the premer eigenfrequency  $f_p^0$  when the chamber length is reduced to small values. The same limit  $f_p^0$  is reached by the second eigenfrequency  $f_{pc}^1$  for large chamber lengths. When the acoustic coupling index  $\mathcal{E}$  takes small but finite values, the premer eigenfrequency  $f_p^0$  calculated as if the cavities were decoupled corresponds to the first eigenfrequency  $f_{pc}^0$  of the system for short chambers and to the second mode  $f_{pc}^1$  for large chambers.

For the long chamber  $L_c = 0.88$  m, the first frequency  $f_{pc}^0 = 183$  Hz is relatively well estimated by the chamber eigenfrequency  $f_c^0 = 191$  Hz while Table 2 shows that the second mode  $f_{pc}^1 = 290$  Hz is close to the premer frequency  $f_p^0 = 281$  Hz as if the two cavities were indeed perfectly decoupled. Table 2 also shows that the two-cavity model remarkably predicts the frequency peaks observed experimentally:  $f_{pc}^0 = 183$  Hz (theoretical) to be compared to 180 Hz and  $f_{pc}^1 = 290$  Hz to be compared to 284 Hz observed experimentally.

A deeper analysis consists in comparing the predicted and measured pressure distributions along the combustor at those frequencies. Results are plotted in Fig. 7(a) and (b) for  $f_{pc}^0$  and  $f_{pc}^1$  respectively. These data are compared to the pressure recorded at the different microphone locations (M1 to M9). Predictions (continuous lines) lie close to the experimental values. The first mode (a) is called a “chamber mode” because its oscillation frequency is determined solely by the chamber length. Unexpectedly, its maximum amplitude is however reached in the premer. The pressure oscillation in the chamber is in phase with the pressure oscillation in the premer and its amplitude at the flame location (M5) is about half that reached at the premer backplane. The second mode is called a “premer mode” because its frequency is only associated to the premer length (and inlet impedance). The oscillation in the chamber is for this mode in phase opposition and significantly weaker than in the premer. For the long chamber, the model allows to predict the experimental data both

**Fig. 7.** Pressure distributions measured (dots) and predicted (lines) along the premixing tube and the long chamber (point 2,  $L = 0.88$  m): (a)  $f_{pc}^0(\text{exp}) = 180$  Hz and  $f_{pc}^0(\text{theo}) = 183$  Hz, (b)  $f_{pc}^1(\text{exp}) = 284$  Hz and  $f_{pc}^1(\text{theo}) = 290$  Hz.  $\theta$  is the phase between the microphones, allowing to plot the envelope of the signal.

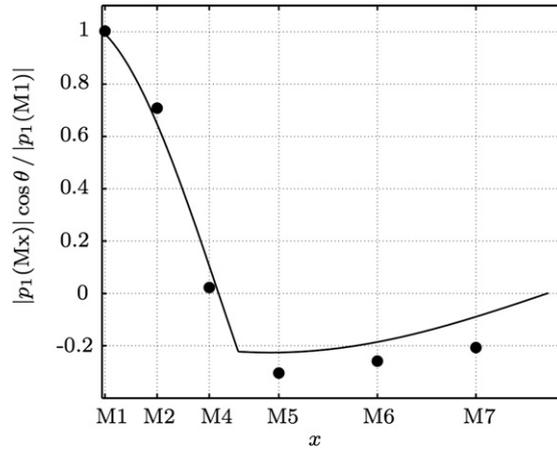

for the frequencies and pressure distributions if the premixer reflection coefficient is correctly determined. In this case, the premixer and chamber behave as uncoupled cavities because the acoustic coupling index  $\mathcal{E} = 0.04$  is small and the eigenfrequencies of the two cavities are significantly different.

The situation for the short chamber  $L_c = 0.55$  m is much more complex even though the coupling index still features the same small value  $\mathcal{E} = 0.04$ . This operating condition is close to the one when the eigenfrequency of the chamber mode  $f_c^0$  exactly matches the eigenfrequency of the premixing tube  $f_p^0$ . This condition is reached for  $L_c = 0.62$  m where veering takes place. This veering phenomenon, well documented in Refs. [29–31], appears when the eigenfrequencies of two sub-systems match each other. In this case, the eigenmodes of the global system are shifted with respect to the frequencies calculated for perfectly decoupled cavities as shown in Fig. 6 even though the acoustic coupling index is small. This phenomenon also appears in the present situation for  $L_c = 0.55$  m when the eigenmodes of the two cavities are close. The two-cavity model yields in this case roots featuring a frequency shift with respect to the uncoupled situation as visible in Table 2. The measured spectrum features also a complex behavior for this chamber length  $L_c = 0.55$  m, where a main frequency peak at 280 Hz was identified together with two low level secondary peaks at 200 and 336 Hz (Fig. 2). The main peak identified at 280 Hz (black dot) is located between the two first computed frequencies (continuous lines) but close to  $f_p^0 = 281$  Hz. The second peak frequency at 336 Hz lies close to the second mode  $f_c^1 \simeq f_c^0 = 322$  Hz, but it is difficult to associate these peak frequencies to one of the eigenmodes of the combustor. The pressure distribution along the combustor is used to clarify the situation for the main peak frequency observed at 280 Hz. Fig. 8 shows the pressure distribution as a function of the combustor location predicted by the model for a frequency  $f_{pc}^1(\text{theo}) = 349$  Hz (continuous line) which is compared to measured data collected at  $f_{pc}^0(\text{exp}) = 280$  Hz (dots). Surprisingly, the two evolutions match quite well. This pressure distribution with fluctuations in the premixer in phase opposition with those in the chamber clearly indicates that the structure of this mode is determined by the premixer cavity  $f_p^0 = 280$  Hz.

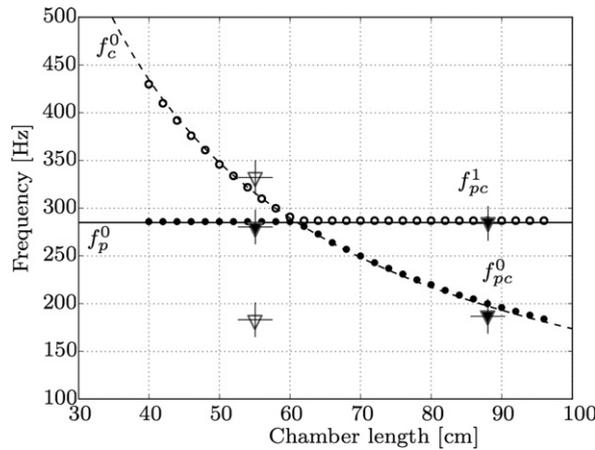

The two-cavity model yields accurate predictions of the eigenmodes of the system when they are clearly separated (long chamber). In this situation, the system behaves like two uncoupled cavities because the acoustic coupling index  $\mathcal{E}$  is small and the frequencies of the so-called independent cavities are sufficiently different. The modes of the system can then easily be determined by examining the modes of each cavity separately. When the modes of these two cavities merge by decreasing the chamber length, veering takes place manifested by a frequency shift of the calculated frequencies with respect to the modes of the cavities calculated separately. It is then not possible to consider uncoupled cavities even for very small values of the acoustic coupling index between the premixer and the chamber (small chamber). It was also shown that in this case experiments yield a complex pressure distribution where it is difficult to match the observed frequencies with the different eigenmodes predicted. Examination of the pressure distribution along the combustor is then a way to elucidate the structure of the different modes observed. In the case explored in this study, it was possible to show that the main peak frequency associated to the short chamber  $L_c = 0.55$  m still corresponds to a premixer mode. In principle this mode is sensitive to slight modifications of the acoustic field in the premixer. To tackle the problem, the five-cavity model is used in the next section to analyze the influence of the injection lines.

## 5. Influence of the feeding lines

One possibility to improve predictions of the eigenfrequencies is to take into account the influence of the injection lines. The two-cavity model analyzed in the previous section showed that there is always a main peak emerging in the measured pressure spectrum associated to the premixer for the long and short combustion chambers. It is then worth examining the influence of the feeding lines acoustics on the pressure distribution. The acoustic impedance in the air feeding pipes was measured 30 cm away from the premixer as shown in Fig. 5. The modulus is roughly constant and equal to 0.4, and the

**Fig. 8.** Pressure distribution measured at  $f_{pc}^0(\text{exp}) = 280$  Hz (dots) and predicted at  $f_{pc}^1(\text{theo}) = 349$  Hz (line) along the premixing tube and the short chamber with the two-cavity model (point 1,  $L = 0.55$  m).  $\theta$  is the phase between the microphones, allowing to plot the envelope of the signal.

**Fig. 9.** Eigenfrequencies of the system predicted by the five-cavity model (circles) as a function of the chamber length. The two modes  $f_{pc}^0$  and  $f_{pc}^1$  are close to the modes of each cavity (premixer: continuous line, chamber: dashed line). Filled triangles represent the resonant frequencies determined experimentally, the empty triangles feature the secondary peaks observed with the short chamber.

phase features a linear growth  $\varphi(f)$  with respect to the frequency (Fig. 4). This reflection coefficient can then be modeled as  $R(y = 0.30) = 0.4 e^{i\varphi(f)}$ , where  $\varphi(f) = \pi \omega / 300 - \pi / 2$ .

Air feeding lines are modeled in the five-cavity model with two 30-cm-long and 3-cm-diameter tubes connected to the premixer axis. The eigenfrequencies of this new acoustic model are determined as a function of the chamber length. Results are plotted in Fig. 9. The computed eigenfrequencies  $f_{pc}^0$  and  $f_{pc}^1$  are represented with black and white circles respectively. These predicted eigenfrequencies are compared to the experimental data (triangles) and to the modes of the premixer (continuous line) and the chamber (dashed line) calculated for a premixer perfectly decoupled from the combustion chamber.

It is striking that the frequency shift observed between the eigenmodes of the combustor  $f_{pc}^0$  and  $f_{pc}^1$  and predictions for the premixer  $f_p^0$  and combustion chamber  $f_c^0$  modes presented in Fig. 6 is now reduced to zero when the acoustics of the feeding lines is taken into account. Modes in this case are well decoupled for the long ( $L_c = 0.88$  m) as for the short ( $L_c = 0.55$  m) combustion chamber. This model first confirms modes predictions for the long chamber where the two main peaks identified in the measurements correspond to  $f_{pc}^0 \simeq f_c^0$  associated to a chamber mode and  $f_{pc}^1 \simeq f_p^0$  associated to a premixer mode. Moreover, it also retrieves a correct frequency of the main peak emerging in the measurements collected for the short combustion chamber. It confirms that in this case this frequency  $f_{pc}^0 \simeq f_p^0 = 280$  Hz is associated to a premixer mode which measured structure and frequency now match with predictions. It is also possible to identify with this improved model that the secondary peak observed at 336 Hz matches  $f_{pc}^1 \simeq f_c^0 = 322$  Hz the mode associated to the combustion chamber. The secondary peak frequency at 180 Hz is not predicted by this model and this point is still under current investigation. One difficulty is that the peak frequencies observed in the spectrum at 180 and 336 Hz are very weak compared to the main frequency 280 Hz. Post-processing of experimental data barely allows to extract their pressure distribution.

It is interesting to examine the reason why veering with the two-cavity model does not manifest the same way with the five-cavity model. This can be done by examining the imaginary component of the roots of the dispersion relation. The

**Table 3**

Complex eigenfrequencies computed with the two models for two different chamber lengths.

	$L_c$	$f_{pc}^0$	$f_{pc}^1$
Two-cavity model	0.55	258 – i2.5	349 – i13
Two-cavity model	0.88	183 – i2.4	290 – i23
Five-cavity model	0.55	283 – i151	318 – i0.77
Five-cavity model	0.88	201 – i0.71	283 – i152

imaginary contribution provides the damping of the mode. A negative value indicates a stable damped mode while a positive value stands for an unstable amplified mode. In the present model, no acoustic source is included and the modes are all damped or marginally stable. Table 3 presents the complex eigenfrequencies computed with the two models investigated. The two-cavity model indicates that damping is always of the same order of magnitude for the two modes  $f_{pc}^0$  and  $f_{pc}^1$  and for all chamber lengths explored. With this model, the two modes are identically damped. The five-cavity model shows that for each chamber length the two modes feature very different imaginary components. In this case, one mode is always more damped than the other. This interesting feature seems to show that, in weakly coupled cavities systems, matching the mode frequencies of the different cavities does not necessarily lead to substantial differences with the modes determined for well decoupled cavities as long as the damping of each mode is sufficiently different.

This novel and original conclusion is under further investigation since more rigorous proofs are still needed. Indeed, the damping of the mode associated with the frequency  $f_{pc}^0$  is strongly negative ( $-151 \text{ s}^{-1}$ ). With this damping, the mode could not be observable experimentally. There is definitively a lack of precision on this value which may come from the modeling. Feeding lines have been modeled by two transverse cavities with an equivalent area of the cross section and connected at the distance  $L_1$  from the back plane. Namely, the similitude is not exact and modifications on either the cavity cross section or the cavity position yield substantial variations of the damping coefficient. Moreover, this large damping questions the validity limit of the measured reflexion coefficients of the feeding lines. Measurements have been carried out *in situ* with a constant amplitude modulation. The acoustic impedances may be strongly modified when the modulation signal is damped. Even if the accuracy of the values is improvable by improving the model, this work mainly shows that modeling efforts are required in order to take into account veering and complex acoustic couplings. Finally, it shows that the damping influences the coupling between cavities. This could be adjusted on combustors by changing wall material, cavity geometry or by designing feeding lines which could be used as dampers. In any case, damping is a parameter very complicated to measure experimentally and a better knowledge of this parameter on practical devices should significantly help in understanding and modeling acoustics in combustors.

## 6. Conclusion

An experimental investigation was conducted on a gas turbine model combustor open to atmospheric conditions featuring a premixing tube connected to a combustion chamber which length can be modified. This system features a weak acoustic coupling index  $\mathcal{E}$  as in many laboratory and practical combustors. It was shown that it is then possible to easily reproduce the acoustic field in the setup when the first eigenmodes of the combustor are well separated. This was the case for the long combustion chamber explored in this study where the first mode is only controlled by the chamber acoustics while the second one is only controlled by the premixer acoustics. Reducing the acoustic coupling index at the design stage of a combustor enables then to easily tune the pressure distribution by independent modifications of the combustion chamber or the premixer elements, except when these frequencies match. This situation was explored here for the short combustion chamber where the premixer and combustion chamber eigenfrequencies were made close to each other. It was shown in this case that it is necessary to analyze the damping of each mode to determine whether they can be considered as decoupled or not. Tuning the damping of the different modes may then be envisaged as a solution to decouple acoustic modes. The whole analysis was conducted without integrating any flame model. This should be done in a near future to see if conclusions are still valid.
