Abstract

For Wireless Personal Area Network (WPAN) systems, resource allocation between several users within a piconet and the coexistence of several piconets are very important points to take into consideration for the optimization of high data rate Ultra Wide Band (UWB) systems. To improve the performance of the Multi-Band OFDM (Orthogonal Frequency Division Multiplex) solution proposed by the Multi-Band OFDM Alliance (MBOA), the addition of a spreading component in the frequency domain is a good solution since it makes resource allocation easier and also offers better robustness against channel frequency selectivity and narrowband interference. The Spread Spectrum – Multi-Carrier – Multiple Access (SS–MC–MA) system proposed in this article offers not only the advantages of Multi-Carrier – Coded Division Multiple Access (MC–CDMA) brought by frequency spreading, but also a more effective dynamic resource allocation in a multi-user and multi-piconet context. These improvements are obtained without increasing the complexity of the radio-frequency part compared to the classical MBOA solution. **To cite this article:** *E. Guéguen et al., C. R. Résumé

Combinaison des techniques OFDM et CDMA pour l'UWB haut débit. Pour les systèmes WPAN (Wireless Personal Area Networks), la gestion des ressources entre plusieurs utilisateurs d'une même picocellule ainsi que la co-existence de plusieurs picocellules sont des points importants à prendre en compte lors de l'optimisation d'un système Ultra Large Bande (ULB) haut débit. Afin d'améliorer les performances de la solution Multi-Band OFDM (Orthogonal Frequency Division Multiplex) proposée par l'alliance MBOA (Multi-Band OFDM Alliance), l'ajout d'une composante d'étalement selon l'axe fréquentiel s'avère une bonne solution pour faciliter la gestion des ressources, qui offre en outre une meilleure robustesse vis-à-vis de la sélectivité en fréquence du canal et des interférences à bande étroite. Le système SS–MC–MA (Spread Spectrum – Multi-Carrier – Multiple Access) que nous proposons, bénéficie non seulement des avantages du MC–CDMA (Multi-Carrier – Coded Division Multiple Access) apportés par l'étalement fréquentiel mais permet également une allocation dynamique des ressources plus efficace dans un contexte multi-utilisateurs et multi-picocellules. Ces améliorations peuvent être obtenues, sans augmenter la complexité du segment radio-fréquence par rapport à la solution MBOA. **Pour citer cet article :** *E. Guéguen et al., C. R. 1. Introduction

Ultra Wide Band (UWB) radio systems are today acknowledged as high potential solutions for Wireless Personal Area Networks (WPAN). Many UWB system approaches are proposed and studied regarding different objectives in terms of service (localization or communication), distance ranges (short or middle) or data rates (high or low) leading to different waveforms. The novelty of these systems consists in the possibility of a non regulated access to the spectral resource, leading to a flexible use of the radio channel for an important number of applications. The standardization process, led by the Task Group 802.15.3a of the Institute of Electrical and Electronics Engineers (IEEE) to define a high data rate physical layer for these WPAN, has seen, during these three last years, the emergence and the confrontation of many solutions designated as ultra wide band solutions. Particularly, the solution known as Multi-Band OFDM (Orthogonal Frequency Division Multiplex), considered by the Multi-Band OFDM Alliance (MBOA) consortium, is currently promoted by the main actors of the general public and components industries [1, 2]. It actually presents some advantages but also some drawbacks. After a critical analysis of the MBOA solution, this article studies the interest of the addition of a Coded Division Multiple Access (CDMA) component to a Multi-Band OFDM signal. Particularly, it is demonstrated that the proposed solution, based on the combination of OFDM and CDMA technologies, offers, for future WPAN, good performance and a great flexibility for resource allocation between users of the same piconet.

2. Diffusion constraints and MBOA solution

In 2002, the Federal Communications Commission (FCC) regulated UWB systems by imposing the spectral mask, illustrated in Fig. 1, to limit transmission power. To be considered as UWB, a signal must have a minimum bandwidth of 500 MHz or a bandwidth to central frequency ratio above 0.2. The power spectral density (PSD) must not exceed -41.3 dBm/MHz. The UWB channel, running from 3.1 to 10.6 GHz, is frequency selective and considered as almost invariant in time. Proposed UWB systems must not disturb existing narrowband systems, like for example Wireless Local Area Network 802.11a standard at 5 GHz.

Nowadays, within the IEEE 802.15.3a standardization authorities, two main approaches have been proposed for the high data rate UWB: a pulse radio solution using DS-CDMA (Direct Sequence-CMDA) ternary codes and the multi-carrier multi-band solution [1]. The latter, supported by the MBOA consortium, proposes to divide the available band into 14 sub-bands of 528 MHz each, as illustrated in Fig. 2.

Each of these sub-bands allows the transmission of an OFDM signal, obtained from a 128 points Inverse Fast Fourier Transform (IFFT). In the first step, studies are focused on the first mode which clusters the first three sub-bands from 3.1 to 4.8 GHz. The multi-user management within a piconet is based on Time Division Multiple Access (TDMA) by using a Time-Frequency Code (TFC). At a given moment, each user occupies one of the three sub-bands of mode 1 [2]. The signal, sampled during the analog to digital conversion, has a limited bandwidth of 500 MHz, leading to low cost components. However, the TFC application introduces frequency hopping from one sub-band to another at the end of each OFDM symbol, thus allowing each user to benefit from frequency diversity owing to the

Data rates in different modes—MBOA solution

Tableau 1

Débits transmis dans les différents modes—solution MBOA

Data rate (Mbit/s)	Modulation	Coding rate (R)	Conjugate symmetric input to IFFT	Time spreading factor (TSF)	Coded bits per OFDM symbol (N_{CBPS})
53.3	QPSK	1/3	Yes	2	100
80	QPSK	1/2	Yes	2	100
110	QPSK	11/32	No	2	200
160	QPSK	1/2	No	2	200
200	QPSK	5/8	No	2	200
320	QPSK	1/2	No	1 (no spreading)	200
400	QPSK	5/8	No	1 (no spreading)	200
480	QPSK	3/4	No	1 (no spreading)	200

width of three sub-bands in mode 1. In addition, considering that each user occupies a given sub-band only one third of the time, it is possible to optimize the transmitted power while respecting the PSD mask imposed by the FCC. Lastly, it is also advised to plan the cohabitation of 4 piconets in a same environment.

2.1. Main parameters of the MBOA solution

Transmitted data rates in each sub-band depend firstly, on the coding rate, as the applied modulation to the different subcarriers of the OFDM multiplex is a quadrature phase-shift keying (QPSK). These different modes corresponding to data rates from 53.3 to 480 Mbit/s are enumerated in Table 1.

The channel code is a 64 state convolutional code with a rate of 1/3 (with generator polynomials $g_0 = 133_8$, $g_1 = 165_8$ and $g_2 = 171_8$) which is punctured to obtain higher rates. For certain modes, each complex symbol and its conjugate symmetric are transmitted into the same OFDM symbol by one subcarrier and its 'mirror' subcarrier, respectively. In this way, the frequency diversity is exploited into each sub-band at the cost of a division by 2 of the useful transmitted data rate. Moreover, for modes corresponding to data rates from 53.3 Mbit/s to 200 Mbit/s, a time spreading of 2 is applied. It consists in the transmission of the same information during 2 consecutive OFDM symbols in order to take advantage of a better frequency diversity, due to the joint application of the TFC. Finally, an interleaving on binary data generated by the encoder is applied in three steps: the symbol block interleaver permutes binary elements within the span of 6 OFDM symbols, the tone block interleaver permutes binary elements transmitted by the subcarriers of an OFDM symbol and the intra-symbol cyclic shifts which consists of different cyclic shifts of symbol blocks within the span of 6 symbols.

The main OFDM parameters of the MBOA solution are summarized in Table 2.

The IFFT size is 128 and the total number of used subcarriers is 122. The useful duration of each OFDM symbol is 242 ns, leading to subcarrier frequency spacing of $\Delta_F = 4.125$ MHz. A zero padding (ZP) guard interval of 60.61 ns duration is added at the end of each OFDM symbol to cope with inter-symbol interference.

The only difference of ZP with the traditional cyclic prefix (CP) is that the CP is replaced by D trailing zeros. This operation, performed on OFDM symbols at the IFFT input, is presented by Eq. (1):

$$\tilde{s}_{ZP}(i) = F_{ZPSM}(i) \quad (1)$$

Table 2
Main OFDM parameters—MBOA solution
Tableau 2
Principaux paramètres OFDM—solution MBOA

Parameter	Value
IFFT/FFT size	128
Sampling frequency	528 MHz
Transmission bandwidth	507.37 MHz
Number of data subcarriers	100
Number of pilot subcarriers	12
Number of guard subcarriers	10
N_{ST} : Total number of used subcarriers	122
Δ_F : Sub-carrier frequency spacing	4.125 MHz (= 528 MHz/128)
T_{FFT} : IFFT/FFT period	242.42 ns ($1/\Delta_F$)
T_{CP} : Zero Padding prefix duration	60.61 ns
T_{GI} : Zero Padding guard interval duration	9.47 ns
T_{SYM} : Symbol interval	312.5 ns ($T_{FFT} + T_{CP} + T_{GI}$)

where $F_{ZP} = \begin{bmatrix} F_M^H \\ 0_{D \times M} \end{bmatrix}$, F_M is the $M \times M$ FFT matrix and $(\cdot)^H$ denotes conjugate transposition, so F_M^H is the IFFT matrix. $s_M(i)$ is the i th $M \times 1$ OFDM symbol at the IFFT input and M is the OFDM symbol length at the IFFT input, in this case $M = 128$.

The input receiver signal is given by:

$$\tilde{x}_{ZP}(i) = H F_{ZP} s_M(i) + H_{IBI} F_{ZP} s_M(i-1) + \tilde{n}_P(i) \quad (2)$$

where H is the $P \times P$ ($P = M + D$) lower triangular Toeplitz matrix with the first column $[h_0 \dots h_L 0 \dots 0]^T$, H_{IBI} is the $P \times P$ upper triangular Toeplitz matrix with the first row $[0 \dots 0 h_L \dots h_1]$ which symbolizes inter-block interference (IBI). The frequency-selective propagation is modelled as a FIR filter with channel impulse response column vector $h = [h_L \dots h_0]^T$ where L is the channel order ($L \leq D \leq M$). $\tilde{n}_P(i)$ is the $P \times 1$ additive white Gaussian noise (AWGN) vector.

The all-zero $D \times M$ matrix $0_{D \times M}$ eliminates the IBI, since $H_{IBI} F_{ZP} = 0_{P \times M}$. Let $H = [H_0, H_{ZP}]$ denotes a partition of the $P \times P$ matrix H where H_0 is the matrix made of the M first columns of H and H_{ZP} the matrix made of the D last columns. The received $P \times 1$ vector then becomes

$$\tilde{x}_{ZP}(i) = H F_{ZP} s_M(i) + \tilde{n}_P(i) = H_0 F_M^H s_M(i) + \tilde{n}_P(i) \quad (3)$$

We can split $\tilde{x}_{ZP}(i)$ in (3) into its upper $M \times 1$ part $\tilde{x}_u(i) = H_u \tilde{s}_M(i)$ and its lower $D \times 1$ part $\tilde{x}_l(i) = H_l \tilde{s}_M(i)$ where H_u (respectively H_l) denotes the corresponding $M \times M$ (resp. $D \times M$) partition of H_0 . So we can form

$$\tilde{x}_M(i) = \tilde{x}_u(i) + \begin{bmatrix} \tilde{x}_l(i) \\ 0_{(M-L) \times 1} \end{bmatrix} = \left(H_u + \begin{bmatrix} H_l \\ 0_{(M-L) \times M} \end{bmatrix} \right) \tilde{s}_M(i) = C_M(h) \tilde{s}_M(i) \quad (4)$$

where $\tilde{s}_M(i)$ is the i th OFDM symbol at the IFFT output and $C_M(h)$ is $M \times M$ circulant matrix with the first row $C_M(h) = \text{Circ}_M(h_0 0 \dots 0 h_L \dots h_1)$. The used of ZP prefix requires to make the operation presented by Eq. (4) and called Overlap and Add (OLA) [3] before the FFT demodulation in order to restore the orthogonality between subcarriers of the multiplex. Also, the obtained result, $\tilde{x}_M(i)$, is the temporal signal at the FFT input, i.e., after correct windowing and OLA operation. The other parts of the receiver are strictly identical to those used with the traditional CP.

ZP allows one to obtain a spectrum with fewer ripples in the useful band than with a traditional CP. Thus the signal can take the exact shape of the PSD mask. The signal shape is optimized, but at the cost of an additional processing in the receiver.

Moreover, an additional guard interval, also of ZP type, of 9.47 ns is added for the commutation from one sub-band to another. The complete solution of the MBOA solution is described in details in [1], and an accurate analysis of its performances is given in [4] in the case of a perfect and real channel estimation.

To summarize, the MBOA solution offers some advantages for high data rate UWB applications, such as the signal robustness against the channel selectivity and the efficient exploitation of the signal energy received within the prefix

Fig. 3. MC-CDMA principle.

Fig. 3. Illustration du principe du MC-CDMA.

duration. The main argument of multi-carrier modulation in general is often quoted in favour of the MBOA solution, when one compares it with the competitive DS-CDMA solution. Indeed, the latter can make use of all the received energy with difficulty, the RAKE finger number being compulsorily limited for complexity reasons. However, the freedom degrees of the MBOA solution are relatively limited in a multi-user and multi-piconet context. In particular, when only the three first sub-bands of the first mode are considered, conflicts appear immediately with the fourth user within a piconet, whereas scenarios going up to 6 simultaneous users have classically to be considered.

3. Why add a CDMA component to the MBOA solution?

Starting from the MBOA solution, some studies have already proposed to add a CDMA component in order to improve system robustness or resource sharing between several users. Indeed, this spreading component allows, in particular, the organisation of the access of several users to a common resource. Taking into account the UWB channel characteristics, frequency selectivity and slow time variation in indoor environment, spreading is generally performed along the frequency axis, leading to MC-CDMA signals [5–8]. The symbols of all users are then transmitted by all the subcarriers, the spreading codes length being lower or equal to the subcarriers number of the OFDM multiplex (Fig. 3). Using another method, [9] compares an OFDM system with an MC-CDMA system for UWB applications at 60 GHz. Generally, these different contributions show that, compared to the ‘traditional’ MBOA solution, beyond a greater facility in the resource sharing in multi-user case, an MC-CDMA system also presents a better robustness against the channel frequency selectivity. Moreover, a spreading component in the frequency domain improves the UWB signal robustness against narrowband interferences. This last point is fundamental for uncontrolled access to the spectral resource considering a flexible use of the radio channel for a great number of different applications. However, in a particular case [5], the authors suggest to use an MC-CDMA signal with a bandwidth $B_W = 1.58$ GHz, equivalent to 3 sub-bands of the MBOA signal, which leads to highly increase the sampling frequency of the analog-to-digital conversion.

4. A new waveform for multi-band UWB: the SS-MC-MA

By applying a spreading code and a multi-access component, we propose in this article an SS-MC-MA (Spread Spectrum – Multi-Carrier – Multiple Access) waveform [10], which is new for UWB applications and offers better performance and more flexibility in the resource management. While considering the WPAN context and UWB channel characteristics, we choose a frequency domain spreading solution. In addition, particularly for technological constraints due to the analog-to-digital conversion, the bandwidth of the transmitted signal at a given moment will be limited to 528 MHz and not 1.584 GHz (equivalent to 3 sub-bands of the first mode) as proposed in [5]. By using a frequency hopping technique over the 3 sub-bands, as proposed by the MBOA solution, it is possible to benefit from the frequency independence due to a bandwidth equal to 1.584 GHz.

4.1. SS-MC-MA principle

With MC-CDMA, resource sharing is realized by the assignment to each user of one or more codes, which are transmitted all over the available bandwidth. Thus, all subcarriers of the whole allocated spectrum transmit the symbols of all users differentiated by their individual code. Then, MC-CDMA can be view as a mono-block system (Fig. 3).

In a multi-block system, spectrum is divided into ‘blocks’ of many subcarriers. Among the possible combinations, the SS-MC-MA solution, illustrated in Fig. 4, consists in assigning to each user a specific block of subcarriers according to a Frequency Division Multiple Access (FDMA) scheme. Code dimension can then be exploited for

Fig. 4. SS–MC–MA system principle illustration.

Fig. 4. Illustration du principe du système SS–MC–MA.

an adaptive resource optimization and sharing (modulation type, data rate, ...). Spreading in the frequency domain leads to diversity gain and, as it is the case for a MC–CDMA signal, improves the UWB signal robustness against narrowband interferers. With a SS–MC–MA signal, symbols are transmitted simultaneously on a specific subset of subcarriers by the same user and undergo the same distortions. Self-interference (SI), which then replaces the multiple access interference (MAI) obtained with MC–CDMA signals, can be easily compensated by mono-user detection with only one complex coefficient per subcarrier.

4.2. SS–MC–MA advantages compared with MBOA solution and MC–CDMA

Let us consider the case of the MBOA standard in mode 1 (Fig. 2).

- Case of three or less users:

In this case, the SS–MC–MA system allows the allocation of a 528 MHz sub-band for each user. This system offers the same performance and advantages as MC–CDMA, while bringing an additional freedom degree compared with the MBOA solution for the dynamic resource allocation, via the allocation of a given number of spreading codes. Another advantage, compared in this case with an MC–CDMA system, is the simpler channel estimation in reception. Indeed, a given subcarrier is distorted by only one channel, the one of the user associated with this subcarrier. With an MC–CDMA system, each subcarrier is corrupted by the different channels of different users, which increases in a considerable way the channel estimation complexity. In that case, each user has to estimate the response of many channels all over the total available bandwidth.

- Case of more than three users:

In the MBOA solution, conflicts appear from 4 users and could cause information losses. In the SS–MC–MA case, code dimension could be exploited to share a same 528 MHz sub-band between 2 or even 3 users if necessary. In that case, the generated signal within a given block corresponds to a MC–CDMA signal, but with a limited number of users per block (2 or even 3).

More generally, in a multi-piconet context, flexibility brought by the resource sharing, by modifying the number of spreading codes assigned to a given user in a given piconet, allows the SS–MC–MA system to offer a more efficient dynamic resource allocation than the MBOA solution.

5. Proposed system description

5.1. System studied

The proposed system is very similar to the MBOA one. Fig. 5 introduces the MBOA transmission chain in continuous lines and, in dashed lines, the added functions to obtain an SS–MC–MA signal. These functions are mainly the Hadamard Transform ('Fast Hadamard Transform': FHT) at the transmitter and the inverse transform (Inverse FHT) at the receiver. In addition, Zero Forcing (ZF) or Minimum Mean Square Error (MMSE) single user detection is applied.

The spreading length L_c is chosen equal to 16 and the number of data subcarriers is reduced from 100 to $6 \times 16 = 96$ for each OFDM symbol. That means that 4 more guard subcarriers are added. Other functions stay unchanged, particularly the OLA operation before the FFT demodulation to restore the orthogonality between subcarriers.

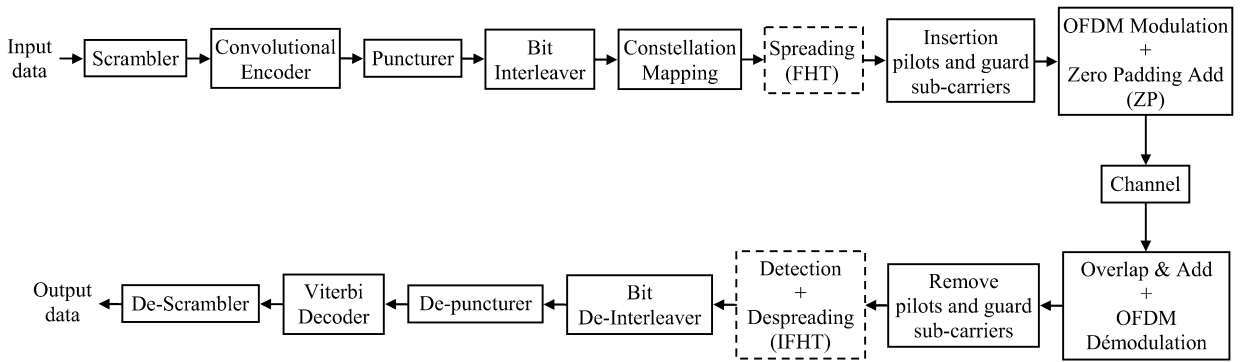

Fig. 5. MBOA transmission chain (SS–MC–MA in broken lines).

Fig. 5. Chaîne de transmission MBOA (SS–MC–MA en traits pointillés).

5.2. Expression of the signals

In the MBOA solution case, the signal generated at the output of the inverse FFT is equal to:

$$S_{\text{OFDM}}(t) = \sum_{i=-\infty}^{+\infty} \sum_{n=-N_{\text{ST}}/2}^{n=N_{\text{ST}}/2} X_n(i) p_c(t - iT_{\text{CP}}) e^{j2\pi n \Delta_F (t - iT_{\text{CP}})} \quad (5)$$

where Δ_F , N_{ST} and T_{SYM} represent subcarriers spacing, the number of total used subcarriers and the spacing between two consecutive OFDM symbols respectively. $X_n(i)$ is a complex symbol, belonging to a QPSK constellation and is transmitted by subcarrier n during the i th OFDM symbol. It represents a data, a pilot or a reference symbol. $p_c(t)$ is a rectangular window defined by:

$$p_c(t) = \begin{cases} 1, & 0 \leq t \leq T_{\text{FFT}} + T_{\text{CP}} \\ 0, & T_{\text{FFT}} + T_{\text{CP}} \leq t \leq T_{\text{FFT}} + T_{\text{CP}} + T_{\text{GI}} \end{cases} \quad (6)$$

In the SS–MC–MA case, complex symbols are converted into P parallel symbols $D_l(i)$ (with $P \leq L_c$), which are transmitted by the same L_c subcarriers. P , representing the load, is for example equal to L_c in the full load case and equal to $L_c/2$ in the half load. $C_l = [c_{l,1} \dots, c_{l,m} \dots, c_{l,L_c}]$ is the l th Walsh–Hadamard orthogonal spreading code. In this case, the waveform is the same as previously, but the complex symbol $X_m(i)$ which is transmitted by the m th subcarrier (m varying from 1 to $L_c = 16$, with $m = n$ modulo(16)) of a block of $L_c = 16$ carriers bound by the same spreading codes of length L_c can be express by:

$$X_m(i) = \sum_{l=1}^{l=P} D_l(i) c_{l,m} \quad (7)$$

where $D_l(i)$ represents the P complex symbols, belonging to a QPSK constellation and which are transmitted by the block of L_c subcarriers considered during the OFDM symbol i . In reception, as in the classical OFDM system case, mono-user detection is simply realized at the output of the FFT by one complex multiplication per subcarrier. ZF and MMSE detection techniques are considered leading to coefficients respectively given by:

$$g_{n,i} = \frac{1}{h_{n,i}} \quad \text{Zero Forcing}$$

$$g_{n,i} = \frac{h_{n,i}^*}{|h_{n,i}|^2 + \frac{1}{\gamma_{n,i}}} \quad \text{MMSE} \quad (8)$$

where $h_{n,i}$ and $\gamma_{n,i}$ represent the complex channel response and the signal to noise ratio for the subcarrier n of the symbol i respectively.

Table 3
Characteristics of wideband channels CM*i*

Tableau 3
Caractéristiques des canaux large bande CM*i*

Characteristics	CM1	CM2	CM3	CM4
Mean excess delay (ns): τ_m	5.05	10.38	14.18

Distance (m)	<4	<4	4–10	10
LOS/NLOS	LOS	NLOS	NLOS	NLOS

5.3. UWB channel modelisation

Wideband propagation channels which are used for UWB systems PHY layer evaluation result from Saleh–Valenzuela model for indoor applications [11]. This ray based model takes into account clusters phenomena highlighted during channels measurements. The multipath channel impulse response for the k th user is given by:

$$h_k(t) = \sum_{m=0}^{M_k} \sum_{p=0}^{P_k} \alpha_k(m, p) \delta(t - T_k(m) - \tau_k(m, p)) \quad (9)$$

where $T_k(m)$ is the cluster m delay, $\alpha_k(m, p)$ and $\tau_k(m, p)$ are the gain and the delay of the path p of the cluster m respectively. The mean excess delay τ_m , and the root mean square delay spread, τ_{rms} , are given in Table 3 for the 4 channel models CM*i* ($i = \{1, \dots, 4\}$).

In the Line Of Sight (LOS) configuration, transmitter and receiver antennas are in direct visibility, contrary to the Non Line Of Sight (NLOS) configuration. Under the assumption that the prefix duration is higher than the channel impulse response spreading and that the subcarriers number N_{ST} is sufficiently large to guarantee the frequency non-selectivity of the channel for each one of these subcarriers, UWB channel can be modelled in the form of N_{ST} sub-channels. In this case, the frequency response for the subcarrier n for the k th user is given by:

$$H_k(n) = \sum_{m=0}^{M_k} \sum_{p=0}^{P_k} \alpha_k(m, p) e^{-j2\pi n \Delta_F (T_k(m) + \tau_k(m, p))} \quad (10)$$

where Δ_F is the subcarrier spacing.

The channel is thus modelled in the frequency domain, and for each sub-band, it is normalized in mean energy for each realization. 100 different realizations are used for each sub-band, one realization being applied along the frame duration. Typical realizations of the frequency responses of CM1 and CM4 models are represented in Fig. 6. As expected, we can note that the frequency selectivity is higher with CM4 than with CM1.

6. Systems performance

Firstly, the performance of the MBOA has been estimated for the different UWB channels. Figs. 7(a) and (b) exhibit the results obtained with both channels CM1 and CM4 in the ideal case of perfect channel estimation and for rates ranged from 480 to 53.3 Mbits/s. These results are given versus E_b/N_0 which is the ratio between energy per useful bit and the noise monolateral spectral density. Note that ZP has been used in simulations and that have thus been considered to compute E_b/N_0 . The performance of the MBOA system for a Gaussian channel with a rate of 320 Mbit/s is also mentioned as a reference.

For each mode, the performances with the two channels are very close. Results are slightly better with CM4 channel, because in that case the received signal benefits from a better frequency diversity. However the frequency domain representation of the channel does not take into account the scarce paths effects that could run over the guard interval and consequently could bring inter-carrier interference. Results versus the E_b/N_0 ratio for the rates of 320 and 160 Mbit/s are almost the same. For the rate of 160 Mbit/s, the spreading over two consecutive symbols does not bring any diversity, as the channel is the same for the two considered symbols.

With the SS–MC–MA system, the number of data subcarriers is reduced from 100 to 96 in order to obtain a multiple of the spreading length equal to 16. The total number N_{ST} of used subcarriers is henceforth 118 and the transmission

Fig. 7. Performances du système MBOA.

bandwidth becomes equal to 490.87 MHz instead of 507.37 MHz. Consequently, with a channel code rate equal to 1/2, the resulting useful data rate is 307 Mbit/s for full load SS–MC–MA system, with $P = L_c = 16$. The SS–MC–MA waveform brings an additional freedom degree for resource allocation. Via the attribution of a given number P of spreading codes, it is very easy to obtain the wanted rate, as shown in Table 4 which gives the different data rates. For example, the 153 Mbit/s rate is obtained with a channel code rate equal to 1/2 and a half load system with $P = 8$, and the 76 Mbit/s rate corresponds to $P = 4$. Furthermore, neither conjugate symmetric function nor time spreading are applied.

The performance of the SS–MC–MA scheme with MMSE single user detection are shown on Figs. 8(a) and (b) for the two channels CM1 and CM4. Note that the spreading codes have not necessarily been chosen optimally in simulations. As is evident from the results obtained at 76 and 57 Mbit/s, the used codes are not favourable regarding the SI, which implies that the 76 Mbit/s scenario outperforms the 57 Mbit/s one. Moreover, a comparison of the two systems is presented in Table 5, which gives the required E_b/N_0 to obtain a BER equal to 10^{-4} for two different bit rates of the MBOA and SS–MC–MA systems for the channel CM1 and CM4. For example, the results obtained with the SS–MC–MA scheme at 76 Mbit/s ($P = 4$) are more attractive than those obtained with the MBOA system at 80 Mbit/s. These results show that the solution of the MBOA consortium, time spreading and conjugate symmetric, to improve the performance of the low bit rate modes are not the most efficient. At higher bit rates, for example

Table 4
Data rates in different modes—SS–MC–MA solution

Tableau 4
Débits transmis dans les différents modes—solution SS–MC–MA

Data rate (Mbit/s)	Modulation	Coding rate (R)	Load P	Coded bits per OFDM symbol (N_{CBPS})
57	QPSK	1/2	3	36
76	QPSK	1/2	4	48
153	QPSK	1/2	8	96
307	QPSK	1/2	16	192
409	QPSK	2/3	16	192
460	QPSK	3/4	16	192

Table 5
Required E_b/N_0 for BER = 10^{-4} versus the bit rate for the MBOA and SS–MC–MA systems

Tableau 5
Rapport E_b/N_0 nécessaire pour un TEB = 10^{-4} en fonction du débit pour les systèmes MBOA et SS–MC–MA

	MBOA		SS–MC–MA	
	80 Mbit/s	320 Mbit/s	76 Mbit/s	307 Mbit/s
CM1	8.2 dB	10.3 dB	7.6 dB	10.2 dB
CM4	8.4 dB	9.85 dB	7.0 dB	9.4 dB

at 307 Mbit/s for SS–MC–MA and 320 Mbit/s for MBOA, this tendency turns out to be less perceptible and both systems perform very close to each other. It is eventually highlighted that the proposed SS–MC–MA solution can be worthy of interest, namely for low bit rates.

7. Conclusion

To improve the performance of the MBOA solution and especially for a better resource allocation in a multi-user context, an adding spreading component in the frequency domain is a good solution which offers a better robustness to cope with the channel frequency selectivity and narrowband interferers. The proposed SS–MC–MA scheme has the advantages of MC–CDMA which are brought by frequency spreading, and also allows a more effective dynamic resource allocation in a multi-user and multi-piconet context. These improvements could be obtained without increas-

ing the system complexity in comparison with the reference MBOA solution. In particular, when the bandwidth of the received signal is still equal to 500 MHz, the radio-frequency part constraints are unchanged compared to the MBOA solution.
